Borrelia burgdorferi is the causative agent of Lyme disease, which affects an estimated 300,000 people annually in the United States. When treated early, the disease usually resolves, but when left untreated, it can result in symptoms such as arthritis and encephalopathy. Treatment of the late-stage disease may require multiple courses of antibiotic therapy. Given that antibiotic resistance has not been observed for B. burgdorferi, the reason for the recalcitrance of late-stage disease to antibiotics is unclear. In other chronic infections, the presence of drug-tolerant persisters has been linked to recalcitrance of the disease. In this study, we examined the ability of B. burgdorferi to form persisters. Killing growing cultures of B. burgdorferi with antibiotics used to treat the disease was distinctly biphasic, with a small subpopulation of surviving cells. Upon regrowth, these cells formed a new subpopulation of antibiotic-tolerant cells, indicating that these are persisters rather than resistant mutants. The level of persisters increased sharply as the culture transitioned from the exponential to stationary phase. Combinations of antibiotics did not improve killing. Daptomycin, a membrane-active bactericidal antibiotic, killed stationary-phase cells but not persisters. Mitomycin C, an anticancer agent that forms adducts with DNA, killed persisters and eradicated growing and stationary cultures of B. burgdorferi. Finally, we examined the ability of pulse dosing an antibiotic to eliminate persisters. After addition of ceftriaxone, the antibiotic was washed away, surviving persisters were allowed to resuscitate, and the antibiotic was added again. Four pulse doses of ceftriaxone killed persisters, eradicating all live bacteria in the culture.

All pathogens studied to date form persisters, dormant variants of regular cells which are tolerant to killing by antibiotics. The ability to produce persisters explains the puzzling recalcitrance of chronic infections to antibiotics that are effective against the same pathogen in vitro. Indeed, many chronic infections are caused by drug-susceptible pathogens (1, 2). The immune system can effectively remove sessile cells from the blood and many of the tissues, and this accounts for the efficacy of antibiotics, including bacteriostatic compounds, in treating uncomplicated infections. When the immune response is limited, the result is often a chronic infection (2). Biofilms are a well-studied example of immune evasion and serve as a paradigm for understanding chronic infections. In biofilms, cells are protected from the large components and by decreasing exposure of antigens (17–19). In B. burgdorferi, the causative agent of Lyme disease, forms drug-tolerant persister cells. Antibiotics kill the regular cells, but dormant persisters survive, and when the concentration of antibiotic drops, they resuscitate and repopulate the biofilm (2). This scenario is supported by our finding of high-persistence (hip) Pseudomonas aeruginosa isolates selected in the course of prolonged antibiotic treatment (6). Isolated from patients with late-stage cystic fibrosis, hip mutants of P. aeruginosa can produce 1,000 times more persisters than the parent strain; this indicates that selection for increased tolerance (rather than resistance) provided the pathogen with a survival advantage. Similarly, hip mutants are selected during treatment of oral thrush caused by Candida albicans (7). In Salmonella enterica serovar Typhimurium, entrance of pathogens into human cells where they are protected from the immune system is accompanied by a sharp increase in persister formation and tolerance to killing by antibiotics (8). In tuberculosis, dormant cells are likely responsible for the need of a lengthy treatment of the acute stage and for the latent form of the disease. Mycobacterium tuberculosis hides from the immune system in macrophages or in granulomas (9).

Borrelia burgdorferi causes Lyme disease, with 300,000 estimated cases annually in the United States alone (10). When treated early with antibiotics, the disease usually resolves (11, 12). If treatment is delayed, the pathogen spreads throughout the body and can cause meningitis, arthritis, and carditis. Meningitis and carditis are mostly self-limited, but Lyme arthritis can persist for years (13, 14). A substantial proportion of patients receiving their first course of antibiotics for Lyme arthritis do not respond fully to a 28-day course of treatment. In such cases, treatment with additional courses of antibiotics is recommended (13, 15, 16). B. burgdorferi avoids immune attack by antigenic variation of surface components and by decreasing exposure of antigens (17–19). In this regard, Lyme disease resembles other chronic infections where the pathogen is protected from the immune system, and persister cells may enable it to survive treatment with antibiotics. In Escherichia coli, the model organism for the study of persisters, dormant cells are formed primarily through expression of toxin-antitoxin (TA) modules. Toxins confer dormancy by either inhibiting protein synthesis or by decreasing the energy level of cells (20–22). TA modules are widely spread among bacteria and are copiously present in some pathogens. E. coli has more than 30 TA modules.
modules and *M. tuberculosis* has more than 75 (23, 24). Interestingly, there are apparently no TA modules in the genome of *B. burgdorferi* (25). Virtually nothing is known about persisters in this species. In this study, we report formation of drug-tolerant persisters in *B. burgdorferi* and describe possible approaches to their elimination.

**MATERIALS AND METHODS**

**Bacterial strains and growth conditions.** *Borrelia burgdorferi* strain B31 5A19 that had been passaged five times in *in vitro* was kindly provided by Monica Embers (26). *B. burgdorferi* was grown in Barbour-Stoenner-Kelly-II (BSK-II) liquid medium in a microaerophilic chamber (34°C, 3% O₂, 5% CO₂). Cultures were started by thawing –80°C glycerol stocks of *B. burgdorferi* (titer, approximately 10⁷ CFU/ml) and diluting 1:20 into fresh BSK-II medium.

BSK-II liquid medium was prepared according to protocol received from Monica Embers’ lab by adding the following ingredients to 400 ml of deionized water and mixing thoroughly: 20 g bovine serum albumin (Sigma), 2 g neopeptone (Fluka), 0.8 g yeastolate (BD), 2.4 g 10X CMRL (US Biologicals), 0.28 g sodium citrate (Fisher), 0.32 g sodium pyruvate (Sigma), 2 g glucose (Fisher), 0.16 g N-acetylglycosamine (Sigma), and 0.88 g sodium pyruvate (Sigma). The pH of the medium was adjusted to 7.6, and 24 ml of rabbit serum (Sigma) was added. The medium was then filtered through a 0.22-μm filter.

Semisolid plating was used to obtain CFU counts (27). First, BSK 1.5× medium for semisolid plating was prepared as described above (27). The following ingredients were added to 1 liter of deionized water (Lab-Chem, Inc.) and mixed thoroughly: 8.33 g neopeptone (Fluka), 4.22 g yeastolate (BD), 9.99 g HEPES acid (Fisher), 8.33 g glucose (Fisher), 1.22 g sodium citrate (Fisher), 1.33 g sodium pyruvate (Sigma), 0.670 g N-acetylglycosamine (Sigma), and 7.66 g sodium bicarbonate (Sigma). The pH of the medium was adjusted to 7.5, and then 83.25 g of bovine serum albumin (Sigma) was added. The medium was stirred for 1 h and then filtered using a 0.22-μm filter. After preparation, 1.5× BSK-1 was stored at 4°C and used within 7 days. On the day of plating, 125 ml of 1.5× BSK was mixed with 6 ml rabbit serum and 19 ml 1× CMRL (97.89 mg/ml) and equilibrated to 55°C. 1.7% agarose (Lonza) was melted and equilibrated to 55°C. When all ingredients had equilibrated to 55°C, 1.7% agarose was added to 1.5× BSK at a ratio of 2:1 (BSK/agarose) to create BSK agarose. Eight milliliters of BSK agarose was dispersed into 60-mm petri dishes as bottom agar and allowed to solidify. For the top agar, 100 μl of the given dilution of *B. burgdorferi* was mixed with 5 ml of 55°C BSK agarose and poured onto the bottom agar plates and allowed to solidify. The plates were incubated in zip-top bags in a microaerophilic chamber (34°C, 3% O₂, 5% CO₂) for 72 h. The lowest growth, and vehicle controls were included on each plate. The MIC plate was covered with Breath-Easy film (Diversified Biotech) and incubated in the microaerophilic chamber (34°C, 3% O₂, 5% CO₂) for 72 h. The lowest concentration of antibiotics that inhibited growth was interpreted as the MIC. All MIC assays were repeated at least twice in triplicate.

**RESULTS**

Characterization of *B. burgdorferi* persisters. The presence of persisters is indicated by a biphasic pattern in a time-dependent killing experiment. The bulk of the population is rapidly killed, followed by a lower rate of death in a subpopulation of tolerant cells (29, 30). In order to determine whether *B. burgdorferi* forms persisters, time-dependent killing experiments were performed with antibiotics commonly prescribed to patients with Lyme disease. Doxycycline is a bacteriostatic protein synthesis inhibitor; amoxicillin and ceftriaxone inhibit bacterial cell wall synthesis and are bactericidal for many bacteria. MICs of doxycycline, amoxicillin, and ceftriaxone were determined (Table 1). Levels of antibiotics close to what is achievable with standard clinically prescribed treatment dosing were chosen to evaluate persister formation in *B. burgdorferi*, and we used colony forming unit (CFU) counts to determine viability.

**Amoxicillin (6 μg/ml, 100× MIC) and ceftriaxone (3 μg/ml, 300× MIC) at clinically achievable levels killed the majority of cells in the first day, after which a slow phase of death followed for the next 6 days (Fig. 1a). This characteristic biphasic pattern of killing is consistent with the presence of drug-tolerant persister cells.**

Previous studies have shown that the persister fraction in other bacteria remains relatively unchanged even as the antibiotic level increases. We sought to determine if *B. burgdorferi* persisters be-
haved similarly in a dose-dependent killing experiment. As the concentration of amoxicillin and ceftriaxone increased, the fraction of surviving cells remained largely unchanged (Fig. 1b and c). Doxycycline is a bacteriostatic antibiotic but at higher concentrations appeared to effectively kill *B. burgdorferi* (Fig. 1d). Again, the fraction of surviving cells did not change significantly with increasing levels of the compound. Thus, *B. burgdorferi* forms persisters capable of surviving very high concentrations of antibiotics, which exceed what is clinically achievable.

Density-dependent formation is a common feature of persisters reported for all pathogens examined so far, including *E. coli*, *Staphylococcus aureus*, *P. aeruginosa*, and *M. tuberculosis* (6, 31–33). In order to test this property in *B. burgdorferi*, samples from a growing culture were removed over time, exposed to a lethal dose of antibiotic for 5 days, and then plated for CFU. There was a characteristic dip in persister levels in the early log phase, which is probably due to the resuscitation of dormant cells carried over from the inoculum (Fig. 2). At the midlog phase, there is a sharp increase in persister levels, which continues as the density of the culture rises. In *E. coli*, once the culture reaches stationary state, complete tolerance is achieved for β-lactams that only kill growing cells (34). In *B. burgdorferi*, we observe a very different picture; amoxicillin and ceftriaxone kill stationary cells fairly well, yet the fraction of persisters continues to increase. One possibility is that this “stationary” culture actually represents a steady state where some cells die and others grow.

Next, we tested whether the *B. burgdorferi* cells surviving antibiotic treatment are drug-tolerant persisters or resistant mutants. For this, colonies produced by the surviving cells were regrown and tested for MIC. The amoxicillin and ceftriaxone MIC remained unchanged, showing that surviving cells had not acquired

![FIG 1 Killing of B. burgdorferi by antibiotics. (a) Time-dependent killing. Antibiotics were added to an exponentially growing culture; samples were taken over time, washed, diluted, and plated in semisolid BSK-II medium for CFU counts. The culture was treated with amoxicillin (Amox) (6 µg/ml) or ceftriaxone (Cef) (3 µg/ml) (n = 9). (b to d) Dose-dependent killing. A late exponential culture of *B. burgdorferi* culture was exposed to antibiotics for 5 days, and surviving cells were determined by CFU count. The culture was treated with amoxicillin (b), ceftriaxone (c), or doxycycline (Dox) (d) (n = 6). Error bars represent standard errors.](http://aac.asm.org/)

![FIG 2 Growth-dependent persister formation in B. burgdorferi. Growth in BSK-II medium was determined by CFU count. Persistor levels were determined by taking samples from the growing culture, exposing to antibiotic for 5 days, and counting CFU. (a) Amoxicillin (Amox) (6 µg/ml) (n = 6); (b) ceftriaxone (Cef) (3 µg/ml) (n = 6). Error bars represent standard errors.](http://aac.asm.org/)
or developed a genetic mechanism for antibiotic resistance. The population grown from the surviving cells produced the same level of persisters as the original population (Fig. 3). These experiments show that *B. burgdorferi* forms typical persister cells.

**Eradication of *B. burgdorferi* persister. (i) Drug combinations.** Some antibiotics act synergistically, such as sulfonamide and trimethoprim, polymyxin and gentamicin, and aminoglycosides and β-lactams (35), and we wanted to see if a combination of compounds known to be active against *B. burgdorferi* would increase the efficiency of killing regular and persister cells.

All possible two-drug combinations of amoxicillin, ceftriaxone, and doxycycline were tested with a late-exponential-phase culture in a time-dependent killing experiment and found to be no more effective than the drugs used individually for killing *B. burgdorferi* (Fig. 4a). Doxycycline actually inhibited the action of amoxicillin. We have shown previously that fluoroquinolones and aminoglycosides can kill nongrowing cells (36, 37), and we next tested these compounds against *B. burgdorferi*. The pathogen is generally poorly susceptible to compounds from these classes.

However, the *B. burgdorferi* MICs for gemifloxacin (fluoroquinolone) and spectinomycin (aminoglycoside) are within achievable human dosing levels, so we chose to test them (38–41) (Table 1). Gemifloxacin and spectinomycin were ineffective in killing *B. burgdorferi* at tested concentrations (Fig. 4b). Combining these compounds also did not improve killing (Fig. 4b).

(ii) Experimental compounds. Having shown that combinations of clinically prescribed antibiotics for Lyme disease are unable to effectively kill persister bacteria, we sought to examine some novel potential antimicrobial agents. We recently showed that acyldepsipeptide (ADEP4), an activator of the ClpP protease, effectively kills persisters in *S. aureus* (42). In the presence of ADEP4, the protease cleaves mature proteins, forcing the cell to self-digest. However, ADEP4 did not have significant activity against *B. burgdorferi* (not shown), which may be due to poor penetration.

We then considered whether knowledge of *B. burgdorferi* biology might be exploited to predict vulnerability to existing approved compounds. *B. burgdorferi* lives under microaerophilic conditions, where the capacity for energy generation is limited by comparison to aerobic organisms. Daptomycin is the only approved membrane-acting antibiotic that disrupts the proton motive force. The *B. burgdorferi* MIC to daptomycin was fairly high, 12 to 25 μg/ml (Table 1), in accordance with published data (43). Daptomycin was highly bactericidal against *B. burgdorferi*, but a remaining subpopulation of persisters survived (Fig. 5), suggesting that *B. burgdorferi* persisters can tolerate a drop in the energy level. Next, we tested vancomycin. This large glycopeptide antibiotic binds to lipid II, a precursor of peptidoglycan, on the outside

**FIG 3** Persistor formation is not heritable. Colonies recovered from a persistor experiment before and after antibiotic treatment were used to inoculate fresh BSK-II medium. The colonies were allowed to grow for 3 days and treated with the same antibiotic used in the original persistor experiment for 5 days (Amox, 6 μg/ml; Cef, 3 μg/ml). Persistor levels of the colonies recovered after antibiotic treatment (right two bars) were not significantly different than the colonies recovered before antibiotic treatment (left two bars) (n = 5). Error bars represent standard errors. Amox, amoxicillin; Cef, ceftriaxone.

**FIG 4** Killing of *B. burgdorferi* with drug combinations. (a) Time-dependent killing of late exponential *B. burgdorferi* cultures exposed to the indicated antibiotics in combination. Amoxicillin (Amox) (6 μg/ml), ceftriaxone (Cef) (3 μg/ml), and doxycycline (Dox) (2.5 μg/ml) (n = 6). (b) Killing of late exponential *B. burgdorferi* exposed to gemifloxacin (Gemi) (1.5 μg/ml) and/or spectinomycin (Spec) (160 μg/ml) singly or in combination (n = 6). An aliquot was taken at indicated time points, washed, diluted, and plated on semisolid BSK-II medium for CFU counts. Error bars represent standard errors.
of the cytoplasmic membrane. Vancomycin is highly effective against Gram-positive bacteria, but does not penetrate across the outer membrane of Gram-negative species. Surprisingly, the vancomycin MIC with *B. burgdorferi* is low, 0.25 μg/ml, which is similar to Gram-positive species. *B. burgdorferi* cells have an outer membrane; the basis for this anomaly is unclear. Vancomycin effectively killed growing cells of *B. burgdorferi*, but not persisters, and was comparable to ceftriaxone (not shown). We also tested teixobactin, a compound we recently discovered, which also binds lipid II (44). At 1.2 kDa, teixobactin is considerably smaller than vancomycin (1.8 kDa), but it did not exhibit good activity in killing *B. burgdorferi* (data not shown).

(iii) Prodrugs. Growth under microaerophilic conditions suggests vulnerability to compounds whose action depends specifically on a low-oxygen environment. Nitroaromatic compounds such as metronidazole are prodrugs that are converted into reactive drugs by bacterial nitroreductases. These enzymes are expressed under anaerobic or microaerophilic conditions and target pathogens living in these environments (i.e., *Helicobacter pylori*, *Clostridium difficile*, and *E. coli*). We found that some nitroaromatic compounds, like nitrofurantoin, are effective in killing *E. coli* persisters (45). However, we did not detect homologs of nitroreductases in the genome of *B. burgdorferi*. The MIC for nitroaromatic compounds (nitrofurantoin, nitrofurazon, and metronidazole) was too high to make them useful agents for killing *B. burgdorferi* persisters (data not shown).

Another compound that depends on a reductive environment for action is the prodrug mitomycin C. Upon entering the cell, mitomycin C is reduced into an active drug which then forms covalent adducts with DNA (46). Originally discovered in a screen for antibiotics, mitomycin C is now used as an anticancer agent. Cancers often create a microaerophilic environment, which together with rapid cell division, accounts for the relatively selective action of mitomycin C against them. Functional RecBC and RecFOR pathways are required to repair DNA damaged by mitomycin C in *E. coli* (46). Interestingly, according to genomic data, *B. burgdorferi* lacks the genes of the RecFOR pathway (47), further suggesting vulnerability to this compound.

Mitomycin C eradicated a late exponential culture of *B. burgdorferi* within 24 h, with no detectable persisters remaining (Fig. 6a). This was observed with a low, clinically achievable dose of the compound, 1.6 μg/ml or 8× MIC. In a dose-dependent experiment, eradication of a late exponential culture was achieved within 5 days with a 0.8 μg/ml (4× MIC) or 1.6 μg/ml (8× MIC) dose of the compounds (Fig. 6b). Finally, mitomycin C was tested against a stationary culture of *B. burgdorferi*. Surprisingly, eradication was achieved with a low dose of 4× MIC within 24 h (Fig. 6c). It appears that a stationary population is more susceptible to this compound than an exponentially growing one.

(iv) Pulse dosing. Apart from identifying compounds capable of killing persisters, it may also be possible to eliminate them with conventional bactericidal antibiotics using pulse dosing. Based on our results, the level of persisters is lowest during early exponential...
Persisters of *Borrelia burgdorferi*

**DISCUSSION**

The presence of drug-tolerant persisters can explain the recalcitrance of chronic infections to antimicrobial therapy, especially in cases when the disease is caused by a susceptible pathogen. While some chronic infections are ancient (leprosy, syphilis, tuberculosis), many cases in developed countries are consequences of otherwise successful medical intervention. Various indwelling devices (catheters, prostheses, heart valves) provide a substratum for biofilms that protect persisters from the immune system (2). Even in bacterial infections that are routinely successfully treated with antibiotics, there is dependence upon the host immune system to control persisting bacteria that are not eradicated by antibiotics. The role of the immune system becomes evident when these same infections involve immunocompromised hosts and antibiotic eradication of the infection becomes much more difficult.

*B. burgdorferi* is a pathogen that can affect immunocompetent hosts. It establishes long-term infections lasting years to lifelong in its natural (i.e., mice) and incidental (i.e., humans) hosts in the absence of antibiotic therapy (14, 48). Treatment in the early stages of disease results in good outcomes. Delays in diagnosis and treatment lead to sequelae that may require additional treatment. For example, patients who develop arthritis, which typically begins after 1 month of untreated infection, often do not respond fully to a first course of 28 days of antibiotics (49). The majority of these patients have evidence of *B. burgdorferi* DNA in their synovial fluid and will respond to additional 1- or 2-month courses of antibiotics (13, 16). A smaller minority of patients referred to as “antibiotic-resistant Lyme arthritis” patients will continue to have arthritis with synovial fluid that is PCR negative for *B. burgdorferi* DNA. These patients typically respond to anti-inflammatory agents such as methotrexate or tumor necrosis factor (TNF) inhibitors. These two groups of patients should be distinguished from patients with “chronic Lyme disease” that exhibit fatigue, myalgias, and arthralgias without clear evidence for the presence of the pathogen. For the first group of Lyme arthritis patients responsive to antibiotics, given that there is no reported resistance to clinically used tetracyclines, β-lactams, and cephalosporins in the pathogen, the need for lengthy courses of therapy is unclear. The presence of persisters cells is one possible explanation, and this is a pattern that is seen in other infections where persister cells are thought to be relevant for disease *in vivo*.

We found that similar to other pathogens, the pattern of killing of *B. burgdorferi* by bactericidal antibiotics is biphasic, with a small subpopulation of surviving persisters. These surviving clones are not resistant mutants; upon regrowth, they form a new persister subpopulation. Also similar to *E. coli*, *S. aureus*, and other pathogens, the density of persisters increases as the culture deviates from strictly exponential growth, reaching a maximum at stationary state. This is probably due to a deterioration of growth conditions resulting in increasing numbers of dormant cells. However, it is notable that the stationary state in *B. burgdorferi* is atypical, as amoxicillin and ceftriaxone continue to kill the majority of cells despite an increase in the level of persisters in the population. Cell wall-acting antibiotics do not normally kill nongrowing cells; one possibility is that stationary state *B. burgdorferi* cultures represent a steady state of growing and dying cells. The ability of β-lactams to kill nongrowing cells was also observed in *M. tuberculosis* where growth (Fig. 2). We reasoned that allowing growth to resume and then retreating them as they enter the exponential phase may kill persisters surviving an antibiotic challenge. Eradication of the culture can then be achieved after several rounds of killing and regrowth. To test this, a culture of *B. burgdorferi* was exposed to amoxicillin or ceftriaxone. The surviving persisters were allowed to resuscitate for a short period of time in fresh medium, and then exposed to the antibiotic again for a second round of killing. Persisters were substantially diminished after four rounds of killing with amoxicillin, and were eradicated below the limit of detection after four rounds of killing with ceftriaxone (Fig. 7). Additionally, we found that a ceftriaxone solution stored under experimental conditions (in BSK-II medium at 34°C, 3% O2, and 5% CO2) does not lose activity, as measured by MICs against *B. burgdorferi*, for up to 20 days. The activity of amoxicillin measured similarly, however, dropped 20-fold over 20 days, which suggests degradation over time. The resulting MIC was still lower than the concentration used in killing experiments. This pulse-dosing experiment shows that a population of the pathogen can be eradicated with conventional antibiotics commonly used to treat the disease.
Sharma et al.

A combination of meropenem and a β-lactamase inhibitor was able to kill viable but nonreplicative cells (50). The authors speculate that peptidoglycan remodeling continues in these nonreplicating cells allowing for the activity of the β-lactam. This is another possible explanation of the killing of stationary-phase B. burgdorferi that we observed with amoxicillin and ceftriaxone.

In a recently published study, Iyer et al. (51) treated two different strains of B. burgdorferi with ceftriaxone and were unable to detect live B. burgdorferi by subculture in liquid medium. However, the cell density in that study was 10^7 cells/ml, and according to our data, persister levels in this early exponential culture are low. In some of the biological replicates treated with ceftriaxone, we have not been able to recover live cells. At higher cell densities, the presence of persisters is unambiguous.

One common strategy for improving elimination of infective agents is to combine existing compounds. For example, β-lactams and aminoglycosides are known to synergize with each other to achieve effective killing of Enterococci (52). We tested combinations of standard antibiotics used in treatment of Lyme disease as well as a combination of a fluoroquinolone and an aminoglycoside, compounds that often synergize and are capable of killing nongrowing cells. However, there was no synergy in killing B. burgdorferi with any of the tested combinations.

We recently described the efficient killing of persisters in S. aureus (42) and in E. coli (45) and tested these compounds against B. burgdorferi. ADEP4, an activator of the Clp protease, causes massive protein degradation in S. aureus, killing regular cells and persisters. However, ADEP4 was not active against B. burgdorferi. We also reported that nitrofurans kill B. burgdorferi persisters more effectively than regular cells (43). This conclusion was based on equating stationary cells with persisters. As follows from our experiments, a stationary culture harbors a small subpopulation of persisters. The actual level of stationary cells apparently surviving treatment by daptomycin in that study was very high, 28%, as determined by LIVE/DEAD staining. Under similar conditions, we detect about 10^6 (0.002%) surviving persisters by CFU count. It appears that LIVE/DEAD staining may be over-reporting the level of live B. burgdorferi cells.

Another weakness of the pathogen is its apparently limited ability for DNA repair. Based on the genome, B. burgdorferi lacks recFOR. In E. coli, RecBC and RecFOR are required for repair of DNA damage caused by mitomycin C, an anticancer drug. Mitomycin C at a low, clinically achievable dose (8× MIC) eradicated B. burgdorferi persisters in exponential and stationary cultures within 24 h. A highly reduced environment activates mitomycin C, and this contributes to its selective action in microaerophilic tumors. While the killing of persisters by mitomycin C is impressive, given the toxicity of this drug, this is more of a proof-of-principle for a compound exploiting the weaknesses of this pathogen rather than a clinically useful agent. Treatment with mitomycin C can result in serious negative side effects, and it should not be used as a model for treatment of Lyme disease. This agent will be useful to examine the possible contribution of persisters to the disease in an animal model of infection.

Another peculiar feature of B. burgdorferi and a weakness of the pathogen is the lack of development of resistance to any antibiotic used to treat Lyme disease. Even attempts to raise mutants resistant to amoxicillin and ceftriaxone in vitro have been unsuccessful. Joseph Bigger proposed an interesting strategy for elimination of persisters in 1944 in the first publication describing these cells (53). The rationale is to add an antibiotic to kill off regular cells, wash it away, and allow the culture to start regrowing, at which point persisters will resuscitate. Reintroducing antibiotics will kill the regrowing bacteria. The argument against pulse dosing is that this protocol invites resistance development. Given that this is not a concern for B. burgdorferi, pulse dosing may be an effective strategy, and we performed pulse dosing with amoxicillin and ceftriaxone. Persisters were eradicated with ceftriaxone in four pulses. These experiments form the basis for testing pulse dosing in an animal model and, if successful, in humans.

While we have identified the presence of B. burgdorferi persisters in cultures of the organism, the mechanisms by which they are able to survive remain unknown. There are multiple pathways of persister formation in other bacteria. The study of persisters so far identified redundant TA modules as a main component responsible for persister formation in E. coli and S. Typhimurium (8, 20, 22). TA modules are widely spread among bacteria but are surprisingly absent from the genome of B. burgdorferi. Other components leading to persister formation in E. coli have been detected as well, including the stringent response (54), various metabolic processes (55, 56), global regulators, and protein stabilizing chaperones (56). Future work will determine if these or other processes are involved in persister formation in B. burgdorferi and if persisters play a role in the pathogenesis of Lyme disease in humans.
